ABSTRACT

The neurodegenerative disorder is a prolonged persistence curse and effect on economic and physical challenges in an aging world. Parkinson has come in the second category of disability disorders and associated with progressive dopaminergic neuronal degeneration with severe motor complications. It is an observation that gradual disease progression causes 70% degeneration of striatal dopaminergic neurons. Globally there are around 7-10 million patients with Parkinson's disease, however, there are huge efforts for therapeutic improvement. According to studies, no single molecular pathway was pointed out as a single etiology to control disease progression due to a lack of targeted therapeutic strategies. Previously implemented symptomatic treatments include L-dopa (L-3,4-dihydroxyphenylalanine), deep brain stimulation, and the surgical insertion of a medical device. This leads to dyskinesia, dystonia and a higher risk of major surgical complications respectively. However, not all the above-mentioned therapies can not regenerate the dopaminergic neurons in Parkinson's disease patients. Recent advances in the field of cellular therapy have shown promising outcomes by differentiation of multipotent mesenchymal stem cells into dopaminergic neurons under the influence of a regenerative substance. In this review, we have discussed the differentiation of dopaminergic neurons by using different cell types that can be used as a cellular therapeutic approach for Parkinson's disease. The information was collected through a comprehensive search using the keywords, "Parkinson Disease, Dopamine, Brain derived neurotrophic" factor and neuron from reliable search engines, PubMed, Google Scholar and Medline reviews from the year 2010 to 2020.

Keywords: Parkinson Disease; Dopamine; Brain Derived Neurotrophic Factor; Neuron.

INTRODUCTION

Parkinson's disease (PD) is a neurodegenerative progressive disorder affecting millions of people worldwide. It is characterized by typical movement disorder including rigidity, tremors and bradykinesia¹. It is identified pathogenically, the Lewy bodies made up of misfolded forms of the protein α -syn².

Pharmacological treatment can be advantageous for many years but prolong use of pharmacological treatment had produced many side effects including, on-off fluctuations and wearing-off phenomenon³, confusion, hypotension, hallucination, orthostatic hypotension, fatigue, brain hemorrhage, infarction, and seizures⁴.

Other innovative modalities had been introduced to PD consisting of gene therapy and cellular therapy. Gene therapy produces enzymes which are responsible for non-synaptically, generating L-dopa (L-3,4-dihydroxyphenylalanine) and dopamine (DA) but this treatment had not proved to be fruitful because this therapy works without any feedback regulation of cellular specificity⁵.

Another new modality is cell-based therapy that has attracted the attention of researchers as being the potentially feasible novel therapies for neurodegenerative diseases. It encompassed the derivation of specific neuronal subtypes lost in the disease and consequent transplantation into exaggerated areas of the nervous system cell types had been used for the differentiation of dopaminergic

neurons for the subsequent transplantation into the Parkinson's patient⁶. In this review, we have discussed the different strategies and cell types used for the differentiation of dopaminergic neurons.

DISCUSSION

Cellular therapy is considered as the elementary unit of regenerative medicine⁷ in the upcoming fields. The goal is to restore the lost function rather than produce a new organ. The differentiated mesenchymal stem cells (MSCs) are plentifully used as a cellular therapy for degenerative diseases. Besides MSCs, other stem cells have also varying differential potential and can be obtained from different sources⁹.

Embryonic Stem Cells (ESCs)

Embryonic stem cells (ESCs) are derived by the blastocyst. The major characteristics have a high capability for potency and self-renewal. ESCs are formed into three germ layers endoderm, mesoderm and ectoderm and the formation of the specific organs. Some progenitor cells retained the organ, can proliferate under injury repair, and can differentiate. These tissue stem cells are found in bone, blood, muscle, adipose tissue, liver, brain, skin, gastrointestinal tract and bone marrow. These cells have the potential to differentiate into three primary germ layers and also sustain in an undifferentiated state and also survive in culture media for a long time¹⁰.

The following transcriptional factors of ESCs e.g., Nanog and Oct4 maintain an undifferentiated state of the stem cells and self-regeneration ability. It was observed that no genetic aberrations are proliferated in the ESC line. Embryonic stem cells are cultured in a media containing the anti-differentiation cytokine in leukemia inhibitory factors (LIF). Withdrawal of the embryonic stem cells from the feeder film consequently caused the development of "embryoid bodies", having all three germs layer¹⁰ however; their use is restricted due to ethical issues and high risk of teratoma formation after transplantation¹⁰.

Induced Pluripotent Stem Cells (iPSCs)

Adult somatic stem cells can convert induced pluripotent stem cells because these cells are genetically reprogrammed and convert into embryonic stem cells (ESC). Now iPSCs are a very important tool for drug development, regenerative medicine and modeling diseases. Further research also showed other numerous benefits, a cell source for Parkinson's disease (PD) replacement as well as the capability to use patient's peculiar cells and consequently reduced the necessity for immuno-suppression. Furthermore, a clinical trial was initiated in Japan, Takahashi's lab, where PD

patients have received human leukocyte antigen (HLA) matched iPSCs derived dopamine neurons. All these researches can be used as assistance for future approach³; however, it has limitations due to the high risk of teratoma formation after transplantation⁹.

Differentiation of iPSCs

Bone marrow mesenchymal stem cells (BMSCs) have great potential to differentiate into neuron-like cell by the presence of the following factor such as hepatocyte growth factors (HGF), vascular endothelial growth factors (VEGF), epidermal growth factors (EGF). These differentiated cells were identified through immunocytochemistry; phase contrast inverted microscopy, immunocytochemistry and transcriptase-polymerase chain reactions to identify the neuronal specific markers¹¹.

Sympathetic neurons can also be derived from induced pluripotent stem cells and embryonic stem cells. Scientists used the helix-loop-helix, Achaete-scute homolog 1 (ASCL1), Paired-like homeobox (PHOX2B), homeodomain transcription factor as important factors for sympathetic neuronal development. However, they also showed the activation of Wingless-related integration site (WNT) signaling pathway¹². Neural differentiation derived from iPSCs by the induction of brain derived growth factors and neuronal cells production with better dendritic, axonal growth and intracellular connectivity can be visible within seven days¹³.

According to Cheng et al. rat bone marrow mesenchymal stem cells differentiate into dopamine neuron like cells by the induction of liver X receptor, causes well differentiation of BMSCs into dopamine neurons¹⁴. This research also showed that when carbonized substrate cultured on human neuronal stem cells, they could be differentiated into matured and specialized neuron cells. Literature also showed that carbon material like graphene oxide promotes the mouse embryonic stem cells differentiation into the dopaminergic neuron, with neuronal gene expression markers¹⁵. Another scientist Velasco et al. differentiated hESCs and iPSCs into mature neurons under the influence of transcription factor either NeuroD1 or Neurogenin 2 within two weeks¹⁶.

Adult Stem Cells

Application of adult stem cell therapy is better compared to the utilization of aborted human embryo's ventral mDA¹⁷ because of immune reactions causes dysfunction of transplanted DA neurons¹⁸. Adult stem cells are obtained from all tissues of the three germ layers and also from the placenta for example, MSCs can be derived from human amnion epithelial cells. These stem cells had various properties such as anti-inflammatory, no rejection issue, and limited differentiation ability. In vitro they are

differentiated into different germ cell layers. Numerous researches had proved in vivo transplantation of adult stem cell repairs of the injured organs, like bone tissue repair and new specialized cell generation. Revascularization of the ischemic cardiac tissue also proved that adult stem cells could release many molecular mediators, with immunomodulatory, angiogenic and anti-apoptotic chemoattractant properties, that stimulate the healing process in culture media⁹. The usage of hMSCs in cell based therapy had involved wide interest in the applications of numerous incurable diseases and had revealed several superior characteristics for therapeutic usage compared to other types of stem cells which are discussed below.

Mesenchymal Stem Cell (MSCs)

Mesenchymal stem cells have prodigious potential with a big source for cellular therapy for neuronal disorders. MSCs are the best example of adult multipotent progenitor cells, derivative from several adult tissues and in vitro they have the ability of self-renewal. The discovery of MSCs from both human and mouse origins can be differentiated into functional neurons and encouraged as a replacement of impaired neurons¹⁹.

The mesenchymal stem cells are spindle-shaped morphologically. They can adhere to tissue culture plastic and grow in culture media and can expand and maintain the multipotent characteristics¹⁹. They are easy to separate, more multilineal differentiation integration into a strong functional shape²⁰ and are unrestricted from ethical problems but they have restricted replicative life span⁹. MSCs release the soluble factors that are significant for cell existence and proliferation, control immune responses and migration to the particular site of injury²¹.

MSCs are obtained from many tissues: adipose tissues, bone, bone marrow, peripheral blood, Wharton's jelly, dental pulp, decidua basalis, amniotic fluid, umbilical cord, placenta, and amniotic membrane, chorionic villi from human placenta, menstrual blood, breast milk, and urine etc²². MSCs with their novel therapeutic properties are the most significant cell type in the era of tissue engineering and cell based therapy²³. Besides their wide availability of proliferative capacity and multipotency, they are the most clinically practiced cell source²⁴. They aid in the release of neurotrophic and angiogenic factors that stimulate neuronal growth-enhancing synaptic connections, promote angiogenesis, neurogenesis, differentiation and axonal remyelination²⁵.

MSCs is the best source for cell-based therapy hence it is safely used for autologous transplantation and showed high differentiation potential²⁶, no tumorigenicity due to paracrine secretion of these

cells, their property exhibits wide clinical potential by regulating apoptosis, angiogenesis, cell differentiation, immunomodulation and extracellular matrix composition¹⁹. The importance of mesenchymal cells, their differentiation ability, potential regeneration of the desire cells, all these unique properties are discussed in this review.

Mesenchymal Stem Cells Based Therapies for Neurological Diseases

Mesenchymal Stem Cells (MSCs) have unique features as compare to other stem cells. These cells have been used in different clinical trials including, Parkinson's disease, Spinal cord injury, Huntington's disease, multiple sclerosis and brain ischemia²⁷.

The human mesenchymal stem cells (hUMSCs) is a high source of progenitor and stem cells containing mesenchymal stem cells. hUMSCs are achieved either from cord blood or the cord tissue. hUMSCs have numerous benefits as compared to other sources of stem cells. MSCs show (Figure 1) various cell surface antigens including CD 105, CD 73, CD90, CD146, and various integrins and adhesion molecules. They can easily be harvested with no harm to the baby and mother. They exhibit high proliferative property and low immunogenicity²⁸. Due to the abundant availability of the umbilical cord, its compatible and effective clinical application can be considered as one of the most plentiful sources of non-embryonic stem cell²⁹.

Differentiation of HUMSCS into Dopaminergic Neurons like Cells

Differentiation of dopaminergic neurons can be achieved by the exposure of extrinsic factors³⁰, including Wnt family members, soluble proteins, growth factors (FGF, GDNF, BDNF, TGF β 2 and EGFR) and chemical inducers (dbcAMP, AA and BHA)³¹. When hUMSCs were cultured in neural containing medium, they produced neural morphologies and expressed neural markers such as nestin, NeuN and glial fibrillary acidic protein²⁷. The Wharton's jelly of the MSCs transdifferentiated into neuron-like cells and they expressed Nestin and Neuro-D1 as neuronal markers by using Valproic acid³².

Previously MSCs from human Wharton jelly was successfully induced by using a glial cell-derived neurotrophic factor and brain derived neurotrophic factors into neurons and auditory hair cells during in vitro experiment³³. Human umbilical cord tissues differentiated into neuron like cells by using nestin, GFAP and synaptic markers: SYN, PSD95, and GAP43³⁴. Mallis et al.³⁵ observed WJ-MSCs differentiated into neural-like cells by using basic fibroblast growth factor and Forskolin, thus differentiating cells into neuron-like cells and astrocytes by cAMP-elevating agents such as Forskolin and 3-isobutyl-1-methylxanthine, and also without the presence of growth factors³⁶.

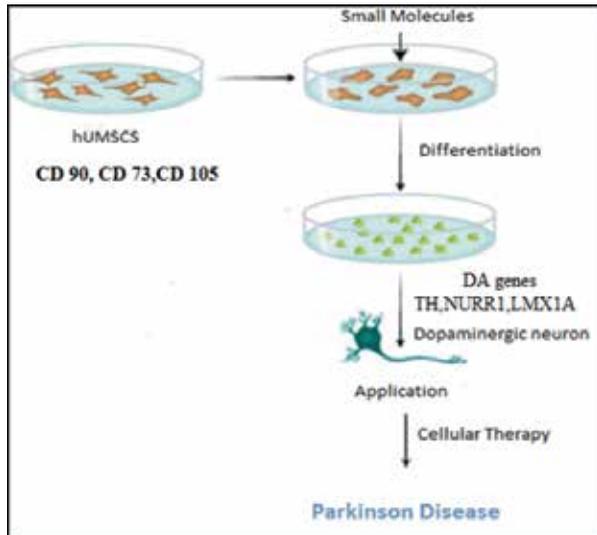

Figure 1: Human umbilical cord mesenchymal cells (huMSCs) differentiation into dopaminergic neurons.

Dopaminergic Neuron Differentiation from Other Sources

Many sources were identified from which dopaminergic neuron differentiation from stem cells was initiated for future applications in regenerative medicine. One of the promising sources is Human olfactory ectomesenchymal stem cells (OE-MSCs) which can differentiate into dopaminergic (DA) neurons by maintaining their plasticity. OE-MSCs were potentiated to differentiate into DA neuron-like cells in vitro by the induction of sonic hedgehog (SHH) signaling pathway, basic fibroblast growth factor (bFGF), fibroblast growth factor 8, Glial cell line-derived neurotrophic factor (GDNF) and brain derived neurotrophic factor (BDNF)²⁹. Human dental pulp stem cell (hDPSCs) differentiation to dopaminergic neurons has been proved a high source. The hDPSCs are obtained noninvasively by deciduous teeth and sustain their multipotency with neuron-like cells and self-renewal properties. Knockout-embryonic stem cell (KO-ES) medium with leukemia inhibitory factor (LIF) was used in which the human pulp cells were expanded. Within 4 days, the neurosphere was formed and further transferred into ITS (human insulin transferrin sodium) and fibronectin media, which further confirmed the selection for Nestin-positive cells. In conclusion, the cells were moved into N-2/ascorbic acid media to promote dopaminergic neurons by the differentiation process and observing the expressions of mesenchymal stem

cell markers and early neuronal markers at different stages³⁷.

According to Lairson et al, fluoxetine stimulates neurogenesis in neural stem cells within the hippocampus. This result showed that there is a link between the regeneration of neurons and their role in reducing the symptoms of depression³⁸. Another research showed that MSCs can be differentiated into osteogenic cells and expressed the bone markers under the induction of osteogenic differentiation medium. In the stage of proliferation, MSCs release laminin, fibronectin and collagen type I in the matrix maturation stage. They secrete alkaline phosphatase and during matrix mineralization expressed the bone genes such as osteopontin proteins and sialoprotein³⁹.

It was also observed that statin molecules are effective in both neuronal differentiation and midbrain neuron specification. Other statin molecules are less potent in neuronal differentiation as compared to mevastatin such as simvastatin⁴⁰. Neural progenitor cells upon differentiation into dopaminergic neurons by mevastatin had shown high expression of dopamine specific genes including TH, Nurr1 and LMX1a compared to other statin molecules. Statin had shown noteworthy effects in both promoting the midbrain neuron specification and neuronal lineage differentiation. Moreover, its efficient mechanism of apoptosis induction in the undifferentiated cells eliminates the chances of brain tumor cancer stem cells⁴¹. Gonzalez et al. reported that neural stem cell differentiation into dopamine neurons in the presence of guggulsterone would be a new approach for the treatment of Parkinson's disease⁴². According to Osborn in the area of transplantation, immune compatibility is very significant and these strategies have fewer advantages to the patients rather than an autologous approach.

Advantages of Autologous Transplantation for Parkinson's Disease

- In Parkinson's patients, no immune suppression by autologous transplantation.
- These are serious immunological reactions of allogeneic transplantation.
- Neural cell autologous approach potentially is greater incorporated the axonal functional³.
- This therapy is effective for neurodegenerative diseases such as Parkinson diseases as shown in Table 1.

Table 1: Overview of advantages and disadvantages of different types of stem cell for cellular therapy of Parkinson's disease⁴³.

Stem Cells	Advantages	Disadvantages
ESCs	High proliferative capacity	High risk of teratoma formation
	High potential to differentiate ant cell types	High risk of immune rejection
		Ethical issues
NSCs	Limited differentiation potential	Restricted proliferative capacity
	Decrease the risk of tumor formation	Low neuronal differentiation capacity
		Ethical issues
MSCs	High proliferative capacity	Differentiated into DA
	No ethical issues	
iPSCs	High proliferative capacity	Risk of teratoma formation
	No ethical issues	Differentiation of DA
	No immune rejection	

CONCLUSION

Therapeutic strategies for neurodegenerative disorders have been found mandatory requirement and have proven to be a major promising achievement for neurological diseases like Parkinson's disease. Damage to the dopaminergic neurons in the Substantia Nigra being the sole cause of movement disorders in PD patients has led to many innovative therapies like drug therapies acting on receptors but then wearing off side effects prevail. Deep brain stimulation also facing different limitations in the regeneration of dopaminergic neurons has led to modalities to be investigated gradually. Emerging options of dopaminergic neuron regeneration by Human Mesenchymal Stem Cells differentiation has been proved the best source of cell-based therapies for neurological diseases. The source of MSC has been exhibited through other sources like Human Dental Pulp cells, Human Olfactory Ectomesenchymal stem cells and hUMSCs, statin through gene expression of dopamine. These examples are a high source of dopaminergic neuron differentiation, which were initiated for future application in regenerative medicine.

ACKNOWLEDGMENTS

I would like to thank Dr. Nabila for her valuable support towards experimental work support.

CONFLICT OF INTEREST

There was no conflict of interest among the authors.

AUTHORS' CONTRIBUTION

HA and SU performed the conceptualization of the study, literature search and prepared the manuscript. ST did the overall evaluation of the review and SH helped in the preparation of the manuscript.
