ABSTRACT

Background: Tibial Diaphyseal fracture (TDF) is the third most common fracture seen in the pediatric population. Titanium elastic nailing (TEN) has been ideal for the management of tibial diaphyseal fractures to prevent complications. Therefore, this study aimed to access the functional outcome of TEN in pediatric Tibial diaphyseal fracture.

Methods: This prospective cohort study was conducted on n=87 skeletally immature patients (6-12 years) at the two hospitals in Karachi from 1st November 2019-30th April 2021 including patients having unilateral, closed Tibial Diaphyseal fracture. The 75 patients (12 of them were lost follow-up) were analyzed in terms of wound infection, union, weight-bearing, limb shortening, rotation, angulation, and range of movement at knee and ankle joints. Paired t-test was used to compare the variables with a p-value < 0.05 was considered statistically significant.

Results: Patients n=75 in this study had a mean age of 8.32±1.92 years with a mean weight of 25.8±6.9. The most frequent cause of injury was traffic accident 49(65.3%), followed by falling 19(25.3%) and 7(9.4%) with other causes. The most common fracture type was transverse 45(60%), followed by oblique 26(34.7%), and the remaining 4(5.3%) had a spiral fracture. All patients were allowed full weight-bearing at 9.8 ±1.5 week. At the end of this study, all patients regained knee and ankle range of motion (p< 0.0001).

Conclusion: Titanium elastic nailing was the ideal procedure for Tibial Diaphyseal fracture in the pediatric population, resulting in a short hospital stay, a rapid rehabilitation without complications.

INTRODUCTION

Pediatric tibial diaphyseal fracture (TDF) is the third most common fracture, contributing to 15% of all pediatric fractures1,2. Pediatric TDF, commonly found in young boys, are mostly oblique or transverse fractures of the middle and distal third of the shaft2,3. Thus, 70% of the fractures are isolated TDF, which are minimally displaced at presentation,
while the remaining 30% are associated with ipsilateral fibular fractures\textsuperscript{1,3}. TDF in younger children is commonly caused due to minor falls and twisting injuries. While in older children it is caused by sports-related trauma or motor vehicle accidents\textsuperscript{5,6,7}.

Treatment is based upon a patient’s age, concomitant injuries, and type of fracture\textsuperscript{5}. Most TDF are treated with cast immobilization and closed reduction, however in cases where these methods do not provide an acceptable reduction in injuries, surgical intervention such as external fixation and plate and screw fixation is used\textsuperscript{7,10}. Over the last decade use of titanium elastic nailing (TEN) has been used to treat pediatric TDF to achieve optimum post-operative results with a low rate of complications\textsuperscript{5,11,12}. TEN as compared to the external fixation offers minimal intrusion using small incisions and provides fewer chances of surgical trauma to the fracture site allowing early union and rehabilitation. External fixation is a heavyweight implant that might hinder the child’s rehabilitation. Hence this method is not preferable in children\textsuperscript{10,12}.

Intramedullary nailing can be of two types rigid or flexible. Although Rigid locked intramedullary nailing provides stable fixation, its use is avoided due to its tendency to damage proximal tibial physis. Hence elastic intramedullary nailing is preferable while treating TDF\textsuperscript{11,14}. Closed reduction with percutaneous Kirschner wire fixation and cast immobilization is useful for unstable, oblique fractures in younger children\textsuperscript{11,12}.

The main objective of this study was to assess the functional and radiological outcome of the TEN in the pediatric age group. Many studies have been conducted on this topic internationally however, in Pakistan not much data is available. Hence this study will be extremely helpful in discovering new treatment options for pediatric TDF. This study will not only give standard guidelines to surgeons regarding treatment but will also ensure the patients’ mental and emotional wellbeing through quick and early mobilization and a complication-free treatment.

\textbf{METHODS}

This prospective cohort research was carried out in the Orthopedic Department of Bantva Memon Hospital, Kharadar and Ziauddin Hospital North Nazimabad campus, Karachi. Using the purposive sampling technique, 87 skeletally immature patients, aged 6-12 years, were selected having unilateral, closed TDF. All patients were admitted through the accident, emergency, and outpatient departments. The duration of the study was 18 months from 1\textsuperscript{st} November 2019 to 30\textsuperscript{th} April 2021. Each patient was followed up for 1 year. All patients with polytrauma, pathological fracture, or previous surgery of limb were excluded from this study. The study was approved by the hospital ethical committee of Bantva Memon Hospital.

All selected patients were clinically examined and radiologically investigated to confirm the diagnosis. Preoperative routine investigations were done. From March 2020 onwards any patient admitted to the hospital for surgery was required to take a PCR Covid-19 test. Patients were explained about the risks and surgical outcome and informed consent were taken. Demographic and preoperative data were collected in Performa which included, age, sex, weight, fracture type, fracture side, cause of injury, and time duration between trauma to surgery.

During the TEN procedures, all patients were placed in a supine position under general anesthesia. Closed reduction was attempted after adequate reduction was achieved two nails with diameter 1/3 to that of the intramedullary canal were implanted through small incisions on lateral and medial sides of proximal tibia metaphysis. The nails were advanced beyond the fracture site bent slightly away from the bone to give stability. Before wound closure was performed, the accuracy of closed reduction was evaluated using the C-arm image intensifier intraoperatively. After three unsuccessful attempts at closed reduction, open reduction was performed with a small lateral incision followed by two Titanium elastic nails to stabilize the fracture.

To maintain stability after the surgery, an above-knee cast was applied for six weeks. Follow-up visits were made at 2, 6, 12, 24 weeks, and then every 3 months for one year. On the 2\textsuperscript{nd} week follow up the Plaster of Paris back slab was removed, the wound was examined, the stitches were removed and the cast was reapplied for further four weeks. On the 6\textsuperscript{th} week follow up the cast was removed and partial weight-bearing was started. Physical therapy was started for initial gait training, more active exercises were started after the callus had reappeared. 6-8 months after the surgery, nails were removed when the fracture line was no longer visible radiologically.

At each postoperative follow-up visit, clinical and radiological assessments were done. The outcome of the data collection includes mean hospitalization stay, full weight-bearing time, rate of open reduc-
Functional Outcome of Titanium Elastic Nailing in Pediatric Tibial Fracture

Results

Patients (n=87) were selected based on inclusion criteria and were operated on, 12 of whom lost follow-up. The final data were collected from 75 patients. 56 (74.7%) were boys and 19 (25.3%) were girls. The average age was 8.32 ± 1.92. The average weight of the patients was 25.8 ± 6.9. The most frequent cause of injury was a traffic accident, which accounted for 49 patients (65.3%), 19 patients had a history of falling (25.3%). The remaining 7 patients had other causes (9.4%). The most common fracture type was transverse, having 45 patients (60%), then was oblique with 26 patients (34.7%) and the remaining 4 patients (5.3%) had a spiral fracture. 43 (57.3%) patients had a left tibia fracture and 32 (42.7%) had a right tibia fracture (Figure 1, Table 1). The average time from accident to operation was 5±1 days. The mean hospitalization time was 3±1 days. In 75(100%) patients closed reduction was successful in the first attempt, while in the other 4 (5.4%) reduction was achieved in the second attempt. None of our patients were treated through open reduction. The fracture union time was 8.6 ± 2 weeks. The full weight-bearing time was 9.8 ± 1.5 weeks.

Follow up period time was an average of 21.27 ± 6.70 months. During the postoperative follow-up visit, there was no case of delayed, nonunion, or nail breakage. Superficial infection was seen only in 2 patients (2.7%) who were treated successfully. Thus, 4 patients (5.3%) experienced nail irritation, which subsided without any treatment. There were 2 cases of limb shortening less than 2 cm. These cases come under satisfactory outcomes. There was no internal or external rotation found in any of the cases (Figure 2). The anterior or posterior angulation found in 6 patients was below 10°, and medial and lateral rotations were less than 5° seen in 4 patients, which according to the protocol were good (Table 2). The movements of knee and ankle joints were within normal limits except in 3 cases, where the range of knee motion was at 60° and after physiotherapy became 85% (p<0.0001, Table 3).

**DISCUSSION**

TDF is the third most common type of pediatric fracture. For decades, cast immobilization has been a standard method for TDF treatment. The basic treatment principles of TDF are based upon the restoration of bone alignment, early mobilization, and rehabilitation after the union. The invention of TEN made a revolution in the management of pediatric TDF. This is a biomechanically ideal method for weight-bearing long bone. The current study showed excellent results, like studies conducted previously. The average time for fracture union is 8.6 ± 2 weeks. The full weight-bearing time was 9.8 ± 1.5 weeks. During the postoperative follow-up visit, there was no case of delayed, nonunion, or nail breakage. Knee and Ankle movements were satisfactory. There was no rotational deformity seen. This study shows good functional outcomes due to quick fracture union, rapid recovery, and rehabilitation.

The results of numerous studies show TEN is the ideal method to treat TDF in children, giving the best results. Economedes et al., reported 19 TDF patients, all of whom achieved bony union at an average of 11 weeks. Five of these patients (26%) experienced irritation at the nail entry site.
Onta et al., studied 18 children, having an average age of 8.2 years, with TDF. The average fracture healing time was 13.3 weeks. 16 children had an angulation of less than 5° and 2 patients had an angulation between 5–10°, which was considered acceptable for their age. Hindley conducted a study of 6-month duration, on 22 patients. 18 patients had an excellent result and the remaining four patients had a satisfactory result. Kamran et al., studied 35 patients all of whom achieved acceptable movement at knee and Ankle joints with no complications. Furtan studied 175 patients, 36 of whom were TDF, which were treated with TEN. Thus, 89% of them had an excellent result, 11% was satisfactory and none of the patients were dissatisfied with their treatment and results. Kubiak et al conducted a study comparing TEN to external fixation with patients having open and closed TDF. In this study, a significant decrease in the fracture union time was reported in TEN as compared to external fixation. Furthermore, superficial pin tract infections were seen in some of the patients with open breaks, and these patients were treated with anti-biotherapy with no requirement for any extra medications. In our facility, we typically leave the TEN finishes on top of the skin because of the restricted delicate tissue support in the proximal tibia, which could clarify the event of the pin tract diseases in some of them and no different patients in comparative examinations. Hence, a second intramedullary TEN with a fitting distance across was embedded through the proximal average of the tibia. Following the assertion of fracture reduction and the placing of the TENs with C-arm.

**CONCLUSION**

Titanium elastic nailing TEN is the treatment of choice for pediatric Tibial Diaphyseal fracture (TDF). It is a minimally invasive technique that ensures early and complete mobilization with a short hospitalization stay. This technique has a minimum complication rate and early rehabilitation which ensures a quicker return to school and their normal routine life is the third most common fracture seen in the pediatric population.

**ACKNOWLEDGEMENT**

We would like to acknowledge the hospital staff, OT technicians, nurses, and physiotherapists for their co-operation and contribution to this study.

**CONFLICT OF INTEREST**

The authors declared no conflict of interest.

**ETHICS APPROVAL**

The study was approved by ethical committee of Bantra Memon Hospital.

**PATIENT CONSENT**

Written consents were taken for participation before the start of the study.

**AUTHORS’ CONTRIBUTION**

MK analyzed and interpreted the patients’ data and constructed the study design. NM analyzed and interpreted the patients’ data and proofread the final article. AF was the major contributor in writing the manuscript MSR carried out the data entry and statistical analysis MS sorted out the references and points for writing the discussion section. SA also assisted in data entry and statistical analysis.
